Abstract

Crimean-Congo Hemorrhagic Fever (CCHF) is the highest widespread, tick-borne viral hemorrhagic fever that affects humans. This virus is endemic in many areas in the world, such as Africa, Asia, and Europe. Nowadays, the incidence of CCHF is increasing rapidly in several countries of the middle-east, with several outbreaks and sporadic cases in human of CCHF, that are reported in several countries in this region.

Keywords  CCHF, Middle east, Iraq

List of abbreviation:  CCHF = Crimean-Congo hemorrhagic fever, ssRNA = Single stranded RNA

Introduction

Crimean–Congo haemorrhagic fever virus (CCHF), genus Nairovirus, family Bunyaviridae, is an enveloped- with a negative-sense ssRNA genome, causes zoonotic disease in many countries of Africa, Asia, Middle East and southeastern Europe \(^1\,^2\,^3\). The distribution of CCHF virus coincides with the distribution of its vector; ticks of genus Hyalomma, makes the spread of these infected ticks into new unaffected areas to facilitate the spread of CCHF virus. The virus circulating in a tick-vertebrate-tick life cycle. These ticks infest on wide spectrum of wildlife animals, and livestock animals, e.g. cattle, sheep, and goat \(^3\,^4\).

Viremia in these livestock is of short lived and low intensity. The livestock animals play a very important role in life cycle of ticks, and in amplifying and transmitting the virus and are, therefore, the focus of veterinary public health, however, animals do not develop clinical signs, while the virus causes significant human illness \(^4\,^5\,^6\,^7\).

Disease characteristics

Infection acquired in humans from bites of tick, or from contact with the infected blood or tissues of livestock or human patients. After a 3-7 days incubation period, the patient can develop severe disease, with a pre-hemorrhagic phase, a hemorrhagic phase, and then a convalescence period. The hemorrhagic manifestations can range from small petechiae to large-hematomas. Bleeding could be from the nose, gastrointestinal tract, respiratory tract, urinary tract, and uterus, with a mortality rate range from 5% to 80% \(^3\,^8\,^9\).

The severity of this infection in humans focus the impact of this zoonotic disease on public health. Serological screening of animal serums for CCHF virus-specific antibodies is very important. Because the virus prevalence in animals is good indicator of the circulating local
virus, these sero-prevalence studies allow the identification of high-risk areas of human infection (10).
Slaughterhouse workers, stockmen, and veterinarians, should be made aware of the disease. They should work on limiting or avoiding exposure of the naked skin to infected blood and tissues, and to avoid tick bites. In general, treatment of livestock could reduce tick density among these animals, and then reduce the of tick bite risks in these animal handlers (10). The infectivity of CCHF virus can be destroyed by boiling low concentrations of formalin and lipid solvents (4).

Migration and Middle East outbreaks
There are 7 CCHF viral genotypes: Africa-1, Africa-2, Africa-3, Asia-1, Asia-2, Euro-1, and Euro-2. According to the region in which they were first recognized and still circulate. However, more than one genotype can be found through multiple countries. This might suggest the migratory pattern of the virus and the appearance of outbreaks (11). CCHF described for the first time in 1944 in the Crimean Peninsula-Russia, and later in the Democratic Republic of the Congo in 1956, which later on gave its name Crimean-Congo. Firstly, this virus was widely reported in Africa, however, in recent years, outbreaks in the Middle East, Asia and Eurasia have become more common (2).
Studies suggested that CCHF virus is a migrating pathogen, however it is not clear this migration is to what extent. Mild et al. in 2010 have analyzed the worldwide migration pattern of CCHF virus, for the first time, their study found that Turkey could be the source of migration to Europe, both to the east and the west, and the United Arab Emirates is the source of migration to the Middle East (12).
In 2002 and 2003, twelve patients in Turkey had proved CCHF virus infection that resemble the virus genotypes found in Russia and Kosovo very closely, and a different genotype from those that caused the outbreak of CCHF in Iran in the year 2002. These data proved that the disease in the affected areas in Turkey was not introduced from Iran whether by a livestock or from an infected tick (13).
In 2009, Chinikar et al. reviewed the history of CCHF in Iran, showed that the disease was detected in Iran since 1970. However, the mortality rate was about 20% in 2000 and then dropped remarkably to 6% in 2007 (14). Iranian molecular studies demonstrated that the Iranian CCHF virus strains were very similar to the Pakistani Strain (15).
A study in Iraq’s Sulaimani province in 2016, showed that CCHF is a rare viral infection in the Sulaimani province, and no proven reported cases, which is mainly due to the ticks’ eradication which was done by the veterinary and agricultural authorities. However, other preventive measures and strategies could be carried out and always monitored by local Sulaimani authorities (16).
The World Health Organization (WHO) reported sporadic human cases and some outbreaks of CCHF virus in the Eastern Mediterranean area, mainly in Iran, Saudi Arabia, Iraq, Oman, Pakistan, Kuwait, and the United Arab Emirates. In these countries, CCHF was increasing in the recent years, and new cases are reported in new areas in this region, with a more geographic extension of this viral disease, which might be linked to the spread of infected ticks by the migratory birds and the trade in livestock. The rise in temperature and decrease in rainfall in the Eastern Mediterranean Region can lead to increase in the distribution of the habitats that are suitable for Hyalomma-ticks, which results in increase in the CCHF virus infection rates (17).
